Health Disparities Among Older Immigrants

in the United States

Abstract

In light of increased immigration to the U.S., our objective is to examine the unique patterns of health status among immigrants aged 55 and over across a wide array of racial and ethnic groups. We explore health disparities within the immigrant population and between immigrants and natives of the same racial/ethnic group. Logistic regression is used to analyze data from the 1992-1995 National Health Interview Survey. Immigrants are less likely than natives to report an activity limitation or to be obese, but more likely than natives to report themselves in poor or fair general health. There are significant differences among immigrants arriving from different countries and between immigrants and natives who are of the same race/ethnicity. For some groups and health measures, a large share of the differences are explained by disparities in socioeconomic status. Older immigrants are not a large enough share of the population, nor do they have distinct enough health status, to substantially alter the aggregate prevalence of health conditions in the total population. However, the diversity in health status within the immigrant population is enormous. These estimates can be used to target populations with especially high rates of obesity and limitations.

Health Disparities among Older Immigrants in the United States

INTRODUCTION

The objective of this paper is to investigate the health status of older immigrants (i.e., foreign-born persons) in the United States. Because of the sheer magnitude of the number of immigrants, their changing racial/ethnic mix, and their differing socioeconomic backgrounds (McCarthy & Vernez, 1997), the health of immigrants may have important implications for the health of the general U.S. population, access to and utilization of health services, and care of the elderly. Furthermore, the health of older immigrants, in particular, may have more of an impact than that of the overall population of immigrants, since most changes in health occur in middle and old age. Using three measures of health status, we compare the health of immigrants to that of natives, with a focus on the population aged 55 and over. First, we examine health disparities within the immigrant population and between immigrants and natives of the same detailed racial/ethnic group. Then, we explore the role that socio-economic status plays in accounting for observed health disparities.

Today, one out of every ten Americans was born outside of the U.S. while just twenty-five years ago only six percent of Americans were foreign born. These changes are even more pronounced in regions such as California, where one out of every four residents is an immigrant (McCarthy & Vernez, 1997). At the same time, the traditional immigrant stream from Europe has been replaced by dominant streams from Latin America and Asia. As recently as the 1960s, the proportion of all newly arriving immigrants who were from Europe was 53 percent, while just 12 percent were from Mexico and 6 percent from Asia. By 1998, the share of new arrivals who were born in Europe had declined to 14 percent, and the share born in Mexico and Asia increased to 20 percent and 32 percent, respectively (U.S. Immigration and Naturalization Services, 1998).

It is well established that there are significant differences in mortality and morbidity among racial/ethnic groups, with blacks, in particular, in worse health than whites. For example, blacks are more likely than whites to suffer and die from heart disease, cancer, stroke and diabetes, to live more years of their life in a disabled state, and to live truncated lives (e.g., Preston & Taubman, 1994; Williams & Collins, 1995; Hummer, 1996; Hayward & Heron, 1999; Rogers, Hummer & Nam, 2000). While the preponderance of research on health and mortality has focused on black-white differentials, studies have found that, in contrast with blacks, Asian Americans tend to have better health, lower mortality, and longer life expectancy than all other racial/ethnic groups, including whites (Rogers et al., 2000; Hayward & Heron, 1999; Hummer, 1996). As a group, Hispanics tend to have an intermediate position, with better health outcomes than blacks and poorer (self-reported general health) or similar health outcomes compared with non-Hispanic whites (Hajat, Lucas & Kington, 2000). Many recent studies on Hispanic health take into account the diversity of this group by examining intra-group differences in health. Mortality and morbidity outcomes vary based on the ethnic origin of the Hispanic group, the health outcome in question, and nativity (Williams & Collins, 1995; Bassford, 1995; Hajat et al., 2000; Rosenwaike, 1987; Rogers et al., 2000; Hummer, Rogers, Nam & LeClere, 1999b). In general, Puerto Ricans have the worst mortality and health outcomes of all Hispanic groups while Cubans and Mexicans have the best (Hajat et al., 2000; Rosenwaike, 1987; Rogers et al., 2000).

Racial/ethnic disparities in health and mortality are largely attributed to group differences in socioeconomic factors such as education, employment, income, occupation, and living conditions, as well as exposure to environmental and occupational hazards that impact health, which is itself influenced by socioeconomic status (Lillie-Blanton & Laveist, 1996; Williams & Collins, 1995; Williams, Lavizzo-Mourey, & Warren, 1994). In fact, many studies find that disparities in education and income explain much, and in some cases all, of the differences in health status between blacks and whites (e.g., Geronimus, Waidmann, Hillemeier, & Burns, 1996; Schoenbaum & Waidmann, 1997; Preston & Taubman, 1994; Behrman, Sickles, & Taubman, 1991; Mutchler & Burr, 1991). Furthermore, group differences in lifestyle and coping behaviors, access to health care (especially early preventive care and health screenings), quality of medical care, health insurance coverage, knowledge about disease conditions and risk factors, and access to or utilization of family and friendship networks also contribute to racial/ethnic

disparities in morbidity and mortality (Sorlie, Rogot, Anderson, Johnson, & Blacklund, 1993; Bassford, 1995; Flaskerud & Kim, 1999; Rogers, 1992; Williams & Collins, 1995).

Only a handful of nationally representative studies examine the health status of immigrants, in general, or the health status of elderly immigrants, in particular. A National Center for Health Statistics report (Stephen, Foote, Hendershot, & Schoenborn, 1994) concluded that the foreign-born population had better health than the U.S.-born population. This result is confirmed for the elderly population by Swallen (1997), who finds lower rates of cancer, lung disease, and diabetes among immigrants. LeClere, Jensen, & Biddlecom (1994) show that (not adjusting for age or sex) native-born persons are more likely to have a work disability, a chronic condition, be in fair or poor health, or have any disability.

A larger set of more specialized studies have also been conducted. These studies have examined selected groups of immigrants (Angel, Angel, McClellan, & Markides, 1996; Angel & Guarnaccia, 1989; Black, Markides, Miller, 1998; Angel & Angel, 1992; Rosenwaike, 1987; Bassford, 1995; Reed & Yano, 1996), analyzed the non-elderly population (Popkin & Udry, 1998; Weeks & Rumbaut, 1991; Hummer, Biegler, DeTurk, Forbes, Frisbee, Hong, et al., 1999a; Alexander, Mor, Kogan, Leland, & Kieffer, 1996; Fuentes-Afflick & Hessol, 1997; Singh & Yu, 1996), or were not national in scope (Kuo & Tsai, 1986; Burnam, Hough, Karno, Escobar, & Telles, 1987; Shetterly, Baxter, Mason, & Hammon, 1996; Hazuda et al., 1988; Rosenwaike & Hempstead, 1990). In general, although there is no overwhelmingly strong pattern that emerges from these studies, the weight of the evidence suggests that immigrants are healthier than natives.

Our study, which focuses on the population aged 55 and over, improves on previous studies by using a nationally representative sample and by analyzing immigrant health at a level of racial/ethnic detail not previously examined. This allows for deeper understanding of the health status of immigrants, which may be beneficial for anticipating and addressing public health challenges in the U.S. as a result of a combination of increased immigration, diversity, and population aging. While a focus on detailed racial/ethnic comparisons is necessary because of the diversity of immigrants, it is also useful to examine immigrants as a whole – regardless of racial/ethnic identity -- to provide an overview of the immigrant population, which we do in this study.

One of the more closely studied determinants of health inequality is socioeconomic status, which may affect health directly or indirectly by, for example, increasing one's ability to purchase medical care or health insurance or reducing the probability of living or working in hazardous settings. The second objective of this paper is to place the spotlight on socioeconomic status by examining the extent to which differences in education and income can explain observed disparities in health status. It is established that there is a substantial gradient in health by socio-economic status (e.g., Preston & Taubman, 1994, Feinstein, 1993). Furthermore, there are substantial differences in the economic status of the foreign- and U.S.-born populations and among foreigners born in different countries (McCarthy & Vernez, 1997). Therefore, differences in socioeconomic status are likely to play an important role in accounting for disparities in health status among these groups.

METHODS

Data

We analyze data from the National Health Interview Survey (NHIS), which is an annual cross-sectional survey of the non-institutionalized U.S. population that interviews about 100,000 individuals in each year. We focus on the population aged 55 and older. To increase sample sizes, we pool data from four years, 1992-1995, resulting in 82,758 natives and 9,296 immigrants for a total sample size of 92,054 observations in our analyses. Individuals whose general health status was unknown, which represented less than 1 percent of the sample, were dropped from the sample.

Unfortunately, information about the specific country of birth of immigrants is not available in the NHIS public use data files. However, two additional questions on race/ethnicity allow us to identify the most likely country of

birth for most immigrants. All respondents, not just immigrants, reported whether their "national origin or ancestry" is one of the following: Puerto Rican, Cuban, Mexican/Mexicano, Mexican American, Chicano, Other Latin American, Other Spanish. In addition, respondents reported their racial group, indicating one of the following: white, black, Indian (American), Eskimo, Aleut, Chinese, Filipino, Hawaiian, Korean, Vietnamese, Japanese, Asian Indian, Samoan, Guamanian, Other Asian Pacific Islander, Other Race, and Multiple Race. Cross-classifying immigrants and natives by their ethnicity and race, we are able to identify immigrants (and natives) of various racial/ethnic backgrounds. Due to small sample sizes, a few race/ethnic categories were grouped together in our analysis. While Spanish-language interviews were conducted (NHIS, 1994), interviews with Asian immigrants may have been conducted in English. This is problematic for some immigrants since selection into the survey based on language may be associated with health status (Jylha, Guralnik, Ferucci, Jokela, & Heikkinen, 1998). Note, however, that the overall response rate for the NHIS was 95-98 percent, depending on the year, suggesting that language-based survey selection may not be substantial.

Many of the racial/ethnic classifications imply that an immigrant was born in a specific country; for example, an immigrant whose "national origin or ancestry" was Cuba was most likely born in Cuba. On the other hand, there may be a substantial number of immigrants who identify their race as "Chinese," but yet they were not born in China. Throughout the paper we will refer to such immigrants as being born in the specific country, e.g., China, but it should be kept in mind that some of these immigrants may have been born and lived elsewhere.

We examined three dimensions of health: self-perceived general health status, existence of an activity limitation, and obesity. General health status is the commonly used self-perceived report. It is a measure of health that is highly correlated with mortality (McGee, Liao, Cao, & Cooper, 1999). The categories asked in the NHIS are excellent, very good, good, fair, or poor. We chose to assign a code of 1 to respondents if they reported being in fair or poor health and 0 if otherwise. Analyses were conducted using various alternative groupings of the five categories, and the qualitative results were robust.

Activity limitation is a leading measure of disability, and respondents are considered to have an activity limitation if they reported that an impairment or health problem limited their ability to complete their primary activity (i.e., working, keeping house, schooling) or any other activity. Survey respondents between 18 and 69 are asked about limitations with working, keeping house or going to school. Survey respondents 70 and older are asked about limitations with activities of daily living such as household chores, shopping and getting around.

We defined a person with a BMI (body mass index) equal to or greater than thirty as obese (NIH, 1998). The BMI is calculated from self-reported weight and height and is the ratio of weight in kilograms divided by the square of height in meters. Obesity is included as a health outcome due to rising public health concern over the increasing prevalence of obesity and the link between being overweight and various chronic diseases including hypertension, stroke and some cancers (NIH, 1998), as well as to mortality from these health conditions (Rogers et al., 2001; Bassford, 1995). Both activity limitation and obesity are measured in our analyses by 0/1 dummy variables.

Analytical Approach

We first examine health disparities between all immigrants and all natives. We then focus on immigrant-native disparities for detailed race/ethnic/ancestry groups. In both sets of analysis, we estimate a series of four logistic regressions for each of our three health indicators. The baseline logistic model (model 1) provides the age-adjusted differences among groups and therefore does not control for socio-economic status. Models 2-4 build on model 1 by including education (model 2), family income and family size (model 3), and then education, family income, family size, region, size of Metropolitan Statistical Area (MSA), and central city simultaneously (model 4). White natives are the reference group in each model. However, we also test for significant difference between immigrants and natives of the same racial/ethnic group in the odds of reporting or having a particular health outcome.

In all four regression models we include demographic controls: an indicator for whether the respondent was female and dummy variables for quinquennial age groups, with 55-60 as the reference. We also include dummy

variables for year of interview, with 1992 as the reference. Finally, an indicator is included for whether the information was (entirely) self-reported versus proxy reported.

Independent variables are incorporated into our models because of sample variation, as well as the association of these variables with the health outcomes in question. Family income and education are negatively associated with poor health outcomes and may help explain health disparities. In our analyses, education is measured by nineteen dummy variables representing years of schooling completed, as reported in the NHIS survey. Family income in the past twelve months, unadjusted for inflation across survey years, is measured by dummy variables for twenty-seven nominal NHIS categories. In order to adjust for families' economic needs, seven dummy variables for family size are included in the models that control for family income. Finally, to control for geographical differences in health and access to health care, we included in model 4 controls for region, the size of the Metropolitan Statistical Area (MSA), and central city residence in the form of 0/1 dummy variables.

One potential limitation of our strategy is that some indicators of socioeconomic status may be endogenous. For example, family income may affect health care utilization, which in turn affects health status. But at the same time, good health may allow people to work harder, longer, and more productively, so their income may be higher. Although this bias may affect the models controlling for income, it is less likely to affect the models that control for education. For the most part, educational investment decisions are made prior to changes in health status (at least among the adults in our sample). However, if there is persistent unobserved heterogeneity, such as genetic or family background environment, that is related to education and health status, then even education may be endogenous. Our maintained hypothesis is that education is exogenous. This is supported by evidence from Behrman (1993) who find that the effects of education (and income) are not sensitive to unobserved heterogeneity. The results controlling for education versus family income will be compared in models that exclude the potentially endogenous control variables of MSA size, region, and central city.

RESULTS

Immigrant-Native Differences in Health

Before turning to the regression analyses where we adjust for socio-demographic factors, it is useful to examine the unadjusted differences in health status among groups. In the population aged 55 and over, the foreign-born report their general health to be worse than the U.S.-born (Table 1). This immigrant-native disparity in general health status is statistically significant and holds true for men and women. Interestingly, the pattern of native advantage in general health status is reversed for activity limitation and obesity. Immigrants are significantly less likely than natives to report an activity limitation. Based on self-reported weight and height, immigrants are also significantly less likely than natives to be obese. For example, 13 percent of the foreign-born are obese relative to 16 percent of the U.S.-born. For both of these health outcomes, the immigrant advantage holds true for men and women.

TABLE 1 ABOUT HERE

The observed disparities in health between immigrants and natives persist once group difference in educational attainment is taken into account (table not shown). Both immigrants and natives report better health at higher levels of education. However, given the same level of educational attainment, immigrants report being in significantly worse general health than natives, while natives are significantly more likely than immigrants to have an activity limitation or to be obese. These findings are supported by multivariate logistic regressions of health outcomes on immigrant status (Table 2, model 1).

TABLE 2 ABOUT HERE

Immigrants have lower socio-economic status than natives (Table 3). Therefore, given the positive association

4

between socio-economic status (as measured by education) and health found in preliminary analyses, the immigrant advantage in activity limitation and obesity actually increases once socio-economic status and other relevant factors are taken into account. In Table 2, model 4, net of all predictors, natives have 35% higher odds of having an activity limitation than immigrants; the odds of being obese are 51% higher for natives than for immigrants. Interestingly, the native advantage in general health reverses so that, in model 4, natives are 15% *more* likely than immigrants to report being in fair or poor health.

Health Disparities Among Immigrants, by Detailed Racial/Ethnic Group

Immigrants (and natives) come from a variety of backgrounds and cultures, and we explore the differences in health status by analyzing immigrants by their country of origin and race/ethnicity. The unadjusted differences among the groups are reported in Table 3. Overall, we find that the Japanese and Chinese are the healthiest immigrant groups on all three health outcomes (Table 3). Mexicans, Puerto Ricans, and immigrants of Other Race (mostly comprised of American Indians, Eskimos, Aleuts and mixed-race people) are consistently among the most disadvantaged. Contrary to the pattern for black natives, black immigrants tend to occupy an intermediate position on health outcomes, having worse health than Asian immigrants, but similar or better health than Hispanic immigrants. Interestingly, black immigrants are less likely than white immigrants to report an activity limitation.

TABLE 3 ABOUT HERE

General Health. Controlling for demographic and other factors, in terms of general health status, Puerto Rican, Other Race and Mexican immigrants continue to be in the worst health of all immigrant groups, the Japanese the healthiest (Table 4 model 1). The odds of being in fair or poor health are 29-52% higher for black, Other Asian, Other Hispanic, and Cuban immigrants relative to white natives. White and Chinese immigrants are not significantly different from white natives on this health outcome, although the odds ratio for the Chinese suggests that they are in better health than white natives (low power due to small sample size for Chinese immigrants may be an issue).

Once group variation in socio-economic status is taken into account, the differences between immigrants and white natives in the odds of fair/poor health are either reduced or disappear in most cases (Table 4, models 2 and 3). In the case of Chinese immigrants, the difference in general health actually becomes significant once education or income is controlled. For most groups, education plays a stronger role than family income in accounting for or reducing disparities in general health. The effect of controlling for education and family income, as well as geographical variation, varies by group, with the result typically being either no change or further reduction in the health gap (model 4). Contrary to this pattern, the initial disadvantages in general health of Mexican, Cuban and Other Hispanic immigrants compared to white natives are actually reversed (model 4).

TABLE 4 ABOUT HERE

Activity Limitation. Controlling for demographic factors, black, Cuban, and Other Hispanic immigrants are at par with white natives in terms of having an activity limitation (Table 5, model 1). Interestingly, once socio-economic factors are also controlled, these three groups are significantly less likely than white natives to have a limitation (models 2, 3 and 4). Consistent with the pattern of disadvantaged health status previously seen, Puerto Rican, Other Race, and Mexican immigrants have higher odds of activity limitation than white natives (1.82, 1.44 and 1.23 respectively). That disadvantage decreases for Puerto Ricans, reverses for Mexicans, and disappears for Other Race once socio-economic factors are controlled (models 2, 3, and 4). White and Asian immigrants are less likely to have an activity limitation than white natives. For the most part, this advantage actually increases with socio-economic and other controls, the exception being Japanese, for whom there is little change across models. For most groups, education appears to have a greater impact on disparities than income, whether in reducing

5

disadvantage or increasing advantage of immigrants.

TABLE 5 ABOUT HERE

While white natives are a natural reference group for immigrants under the assimilation model, Table 6 offers a more direct analysis of differences in activity limitation among immigrants. That is, we report a subset of the results of statistical tests done to determine whether health status is different among various groups. The shaded area above the diagonal reports tests based on model (1), with the tests based on model (4) reported in the remaining portion of the table. For example, the comparison between white immigrants and Cuban immigrants is not statistically significant at the 0.05 level when adjusting only for age, sex, survey year, and proxy reporting, i.e., model (1). But the difference is statistically significant (as indicated by "*" in Table 6) once education and income are adjusted in model (4).

Controlling only for demographic factors (model 1), we find that, initially, there is no significant difference among white, black, Other Asian, Cuban, and Other Hispanic immigrants. These groups are in better health than Puerto Rican and Mexican immigrants (who are significantly different from each other), but in worse health than Chinese and Japanese immigrants (who are at par with each other). Once socioeconomic and other factors are taken into account (model 4), gaps in health appear for some groups. For example, while whites and blacks remain at par, whites become significantly different from Other Asians, Cubans, and Other Hispanics who now seem to be in better health. For other groups, model 4 controls explain away initial differences. For example, once socioeconomic and geographic factors are controlled, there are no observed health gaps among the Japanese, Mexicans, Other Asians, Cubans, and Other Hispanics. Chinese immigrants are now in the best health; Puerto Rican immigrants remain in the worst health.

TABLE 6 ABOUT HERE

Obesity. Black, Other Race, and Cuban immigrants are no more or less likely than white natives to be obese, and this finding persists across models (Table 7). Mexican immigrants and island-born Puerto Ricans are the most disadvantaged groups, having 66.6% and 44.9% higher odds of obesity relative to white natives, respectively. This disadvantage disappears for Puerto Ricans and is reduced for Mexicans once socio-economic factors are controlled (models 2 and 3). The gap in health between Mexican immigrants and white natives is completely accounted for when education, income, and geographical factors are simultaneously controlled (model 4). Japanese immigrants are the least likely to be obese with odds that are 96% lower than those of white natives, and this finding is persistent across models. The gap in health between white natives and Chinese or Other Asian immigrants is also fairly large. The odds of being obese are 87% and 71% lower for Chinese and Other Asians immigrants, respectively. The differences in health between these groups and white natives only increase with controls for socio-economic status.

According to Table 8, there are no significant differences in health among white, Other Race, Cuban and Other Hispanic immigrants in terms of obesity (model 1). These groups are in worse health than the Chinese and Japanese, who themselves are at par and in the best health. The picture is more complex for other groups. For example, there is no health gap between black immigrants and Other Race, Puerto Rican, Cuban and Mexican immigrants. However, Cubans are significantly different from both Mexicans and Puerto Ricans, who themselves are at par with each other. Once socioeconomic and geographic factors are controlled, some disparities disappear. For example, black and white immigrants are now at par, as are whites and Puerto Ricans. The gaps in health among Hispanic groups, with the exception of Other Hispanics, also disappear. For the most part, however, the patterns of disparity observed in model 1 persist even when socioeconomic status is taken into account.

TABLE 8 ABOUT HERE

6

Immigrant-Native Health Disparities, Within Detailed Racial/Ethnic Group

Comparing immigrants and natives within each detailed racial/ethnic group (Table 3), we find that for all groups (except Puerto Ricans), immigrants have the same or lower prevalence of activity limitation than natives, and immigrants are less likely to be obese than natives. However, for all groups (except blacks), immigrants are more likely to be in fair or poor health. For each health outcome, the immigrant-native gap ranges from 0% to 4% in most groups. However, the immigrant-native disparities are particularly large for Puerto Ricans and blacks. Among Puerto Ricans, there is an 18 percentage point difference in favor of the mainland-born for self-reported general health and a 13 percentage point difference in favor of the mainland-born for activity limitation. Among blacks, there is a 15 and a 13 percentage point difference in favor of immigrants for general health and activity limitation, respectively. The gap between black immigrants and natives is also large for obesity (9 percentage points in favor of immigrants).

We further examine health disparities by detailed racial/ethnic group with multivariate logistic regressions for each health outcome in Tables 4, 5, and 7. In addition to the coefficient estimates, the tables report statistical tests for the difference between immigrants and natives within the same racial/ethnic group, with a statistically significant difference at the 0.05 level indicated with a superscript "*y*." The analyses reveal a persistent and significant gap in health between immigrant and native blacks on all three health outcomes. Black immigrants have the same or better health than white natives, while black natives are disadvantaged regardless of controls for group differences in demographic, socio-economic, geographical and other factors. White immigrants have the same odds of being in fair or poor health but lower odds of having an activity limitation or being obese relative to white natives. As with blacks, any observed group differences (or lack thereof) hold across all models. There is no significant difference in health on any of the three outcomes between immigrants and natives among Asian groups, regardless of model controls, with the exception of Other Asians (a heterogeneous group). In terms of obesity, Other Asian immigrants have a significant and persistent advantage in health relative to their U. S.-born counterparts.

Among Puerto Ricans, there is no significant difference in health between the island-born and the mainland-born in terms of obesity. However, natives are less likely to have an activity limitation. This disparity in activity limitation is completely explained by group differences in education or income. Natives are also less likely to report being in fair or poor health, a disparity explained solely by educational differences between the two groups.

Net of demographic factors, Mexican immigrants and natives are not significantly different from one another in terms of obesity, activity limitation or general health (Tables 4, 5 and 7, model 1). However, while parity holds true across subsequent models for obesity, disparities in general health and activity limitation become evident once socio-economic factors are controlled. Immigrants are less likely to be in poor health only in models where education is controlled. They are also less likely to have an activity limitation when either education or income is controlled.

For all three health outcomes, Other Hispanic immigrants and natives are initially at par, net of demographic factors. However, in terms of activity limitation and obesity, a gap in health - in favor of immigrants - becomes apparent once either education or income is controlled. A significant difference, again in favor of immigrants, is observed for general health status only when income, education and geography are simultaneously controlled. This finding on general health mirrors that for Cuban immigrants and natives, who are otherwise at par - across all models - on obesity and activity limitation outcomes. Other Race immigrants and natives have no difference in general health and activity limitation, regardless of controls. However, Other Race immigrants are less likely to be obese than natives once either education or income is controlled.

DISCUSSION

The rise in immigration and the increase in health care costs have focused greater attention on health care utilization, health insurance coverage, and health status of immigrants. This paper has examined the latter by painting a broad picture of the health status of immigrants born in various countries, comparing their situation with immigrants born in other countries and U. S.-born persons of similar racial and ethnic backgrounds. As expected

given the variation in socioeconomic status among groups, there are large disparities in health status among different immigrant groups. In general, Asian immigrants have the best health outcomes, while Puerto Ricans, Mexicans and "Other Race" persons the worst. However, once socioeconomic and geographic controls are included in multivariate analyses, Mexican immigrants' disadvantaged status relative to white natives reverses to one of immigrant advantage for general health and activity limitation and changes to parity for obesity. Mexican immigrants continue to be significantly different from most other immigrant groups across health outcomes. The health disadvantage of Puerto Rican immigrants relative to white natives is usually explained by socioeconomic and geographic controls (with the exception of general health). Likewise, gaps in the odds of being obese between island-born Puerto Ricans and some of the other immigrant groups disappear with controls; however, most differentials between Puerto Rican and other immigrant groups persist where activity limitation is concerned.

The differences between immigrants and natives of the same racial/ethnic background are large and usually in favor of the immigrant. One of the most striking differences is between black immigrants and natives, with natives much more likely to be in poorer health across all health outcomes even after controlling for socioeconomic and geographic variables. Within the Asian population, the Chinese and the Japanese are least likely to report an activity limitation or to be obese. In most cases, Asian immigrants and natives have similar health outcomes. Hispanic immigrants and natives, however, tend to differ significantly on most health outcomes. Some of the differences in health - in favor of immigrants - can be attributed to socioeconomic status, although only for a few groups and comparisons can the majority of the gap be accounted for by these factors.

An important finding is that, among groups with a disadvantage in health, controlling for educational attainment alone substantially reduces, reverses, or completely accounts for the gap in health relative to white natives. This is the case, for example, with Cuban immigrants and natives and Mexican immigrants in terms of self-reported health; Mexican natives in terms of activity limitation; and island-born Puerto-Ricans in terms of obesity. Income has less of an impact than education in reducing disparities, and by itself, eliminates disparities relative to whites only for Other Asian immigrants. Differences in the characteristics of place also matter for some groups. Geography, together with socioeconomic status, completely account for disparities in health for some groups, such as Mexican natives in terms of self-reported health; island-born Puerto-Ricans in terms of activity limitation; and Mexican immigrants in terms of obesity; and substantially reduces the gap in health for others. So, education and geographic context seem to matter most for addressing racial/ethnic and immigrant-native gaps in health in our analyses.

One potential explanation for our findings of immigrant advantage in health is that there may be positive selection on health among immigrants (see, for example, Swallen, 1997). Those who migrate to the U.S. may be healthier than those who remain in the country of origin, and so they compare favorably to the U.S.-born population. It is also possible that there is selective survival in that less healthy immigrants may return to their country of origin, leaving the sturdiest immigrants as a comparison for the native population. Explaining the causes for the remaining differences across the large number of groups we have examined here is a high priority for future research (Abraido-Lanza, Dohrenwend, Ng-Mak, & Turner, 1999).

Given its large sample sizes, the NHIS is the best dataset to paint a broad picture of health status among various immigrant groups. However, the NHIS (and most all other national data on health status of immigrants) has limitations. Health measures are not clinically confirmed, and it has been shown that language of interview effects self-reported health status (Angel & Guarnaccia, 1989). We have used both subjective (i.e., general health status) and more objective measures (i.e., obesity) to address this issue, in the absence of clinical assessments.

Another limitation is that the NHIS data include only a proxy for acculturation, duration of time in the U.S., which is not an ideal measure in cross-sectional studies according to Borjas (1985). We extended model 4 for each of the four outcomes by including indicators for years in the U.S. (see Appendix Table). While there are some minor changes in effect sizes and significance levels, for the most part, our substantive conclusions remain the same. There are a few exceptions. Black immigrants, Other Hispanic immigrants, and white immigrants were less likely to have activity limitations than white natives, but once controls for duration were added to the model, this advantage disappears. Also, island-born Puerto Ricans, who were at parity with whites in Table 5, model 4, are again

disadvantaged once duration is added to the model. We plan to further investigate the effects of acculturation in the U.S. on various health outcomes of immigrants with longitudinal data.

Finally, our measures of socioeconomic status are limited and only include completed years of schooling and a categorical indicator of total household income from all sources. Information on wealth, income in other years, and parental background are not available. Despite this latter limitation, measured socioeconomic status plays an important role in explaining the differences in health among some groups, and future work will investigate the proximate components of this link. Socioeconomic status and geographic context did not completely account for disparities in health for several groups, and we plan to extend our analyses to include other determinants of health, such as diet and exercise, using other NCHS data.
